Executive Summary

Geochemical modeling results of water extracts from simulated immobilized low-activity waste (ILAW) glasses, placed in lysimeters for eight years suggest that the secondary phase reaction network developed using product consistency test (PCT) results at 90 °C may need to be modified for field conditions. For sediment samples that had been collected from near the glass samples, the impact of glass corrosion could be readily observed based upon the pH of their water extracts. For unimpacted sediments the pH ranged from 7.88 to 8.11 with an average of 8.04. Sediments that had observable impacts from glass corrosion exhibited elevated pH values (as high as 9.97). For lysimeter sediment samples that appear to have been impacted by glass corrosion to the greatest extent, saturation indices determined for analcime, calcite, and chalcedony in the 1:1 water extracts were near equilibrium and were consistent with the secondary phase reaction network developed using PCT results at 90 °C. $\text{Fe(OH)}_3(s)$ also appears to be essentially at equilibrium in extracts impacted by glass corrosion, but with a solubility product ($\log K_{sp}$) that is approximately 2.13 units lower than that used in the secondary phase reaction network developed using PCT results at 90 °C. The solubilities of $\text{TiO}_2(\text{am})$ and $\text{ZrO}_2(\text{am})$ [(am) indicates an amorphous phase] also appear to be much lower than that assumed in the secondary phase reaction network developed using PCT results at 90 °C. The extent that the solubility of $\text{TiO}_2(\text{am})$ and $\text{ZrO}_2(\text{am})$ were reduced relative to that assumed in the secondary phase reaction network developed using PCT results at 90°C could not be quantified because the concentrations of Ti and Zr in the extracts were below the estimated quantification limit. Gibbsite was consistently highly oversaturated in the extract while dawsonite was at or near equilibrium. This suggests that dawsonite might be a more suitable phase for the secondary phase reaction network than gibbsite under field conditions. This may be due to the availability of carbonate that exists in the Hanford sediments as calcite. A significant source of carbonate was not available in the PCTs and this may account for why this phase did not appear in the PCTs. Sepiolite was consistently highly undersaturated, suggesting that another phase controls the solubility of magnesium. For samples that were most impacted by the effects of glass corrosion, magnesite appears to control glass corrosion. For samples that show less impact from glass corrosion, clinochlore-7A or saponite-Mg appears to control the magnesium concentrations. For zinc, it appears that zincite is a better candidate than $\text{Zn(OH)}_2\gamma$ for controlling zinc concentrations in the extracts; however, in some samples all zinc phases considered were highly oversaturated. As a result the phase that controls zinc concentrations in the lysimeter extracts remains uncertain.

1.0 Introduction

Performance assessment calculations for immobilized low-activity waste (ILAW) glass to be disposed at the Hanford Site depend on simulations of long-term glass corrosion behavior and contaminant transport that are being performed via reactive chemical transport modeling (e.g., STOMP simulations). Confidence in the underlying physical and geochemical processes that are included in conceptual models and are being simulated by computer codes can be significantly enhanced through the use of carefully controlled field testing. Field-testing allows the Integrated Disposal Facility performance assessment (IDF-PA) program to obtain independent and site-relevant data on glass corrosion at a length scale more relevant to the actual disposal system. As a result, these field test data can be used to validate the models used to forecast the long-term behavior of the glass waste form and the resulting environmental impacts.

Although lysimeters have several disadvantages, they are the logical choice for field-testing glass corrosion and contaminant transport for IDF-PA model validation. The lysimeter system provides an approach to combine the low-activity waste (LAW) glass, Hanford soil, and other engineered materials in a well-controlled test at a length-scale that is not practical in the laboratory. The walls of the lysimeter: 1) form a physical boundary in the system being studied that defines a fixed volume for calculating water storage and tracer mass balance, and 2) restrict the geometry of flow within the lysimeter to essentially one dimension. Interpretation of complex temporal variations in tracer release and transport is much simpler in one spatial dimension. The field-scale affords the opportunity to monitor contaminant release and transport in time and space that is not possible in laboratory experiments.

In 2002 and 2003 a set of lysimeter field studies was initiated to field-test glass corrosion and contaminant transport for IDF-PA model validation (Meyer et al. 2001; McGrail et al. 2003). The lysimeter field studies were conducted in existing lysimeters at the Field Lysimeter Test Facility (FLTF) at Hanford. In fiscal year 2010 (FY 2010) after approximately eight years of testing, all three of the lysimeters were excavated and soil samples and glass cylinders retrieved. Portions of the solids from all three lysimeters were archived for potential future solids and solution characterization. In FY 2013 experimental data were collected to determine the elemental concentration profiles of samples obtained from lysimeters to determine the flux of elements from the glass samples as a function of depth. This was accomplished with 1:1 water extracts on sediment samples collected from sediment cores taken from the lysimeters (Pierce et al. 2013). Mineralogical and surface analysis of a select number of glass samples collected from the lysimeter facility was also completed. This work included X-ray diffraction (XRD) and scanning electron microscopy (SEM) analyses. In FY 2014 geochemical modeling of the water extracts was conducted to assess the applicability of the currently used suite of secondary phases. This work consisted of conducting saturation index (SI) calculations on the 1:1 water extracts of sediment samples collected from sediment cores taken from the lysimeters. These results are reported here along with a discussion regarding the implications of the results.

1.1 Quality Assurance

This work was conducted with funding from Washington River Protection Solutions (WRPS) under contract 36437-161, ILAW Glass Testing for Disposal at IDF. The work was conducted as part of Pacific Northwest National Laboratory (PNNL) Project 66309, ILAW Glass Testing for Disposal at IDF.

All research and development (R&D) work at PNNL is performed in accordance with PNNL's Laboratory-level Quality Management Program, which is based on a graded application of NQA-1-2000, *Quality Assurance Requirements for Nuclear Facility Applications*, to R&D activities. To ensure that all client quality assurance (QA) expectations were addressed, the QA controls of the WRPS Waste Form Testing Program (WWFTP) QA program were also implemented for this work. The WWFTP QA program consists of the WWFTP Quality Assurance Plan (QA-WWFTP-001) and associated QA-NSLW-numbered procedures that provide detailed instructions for implementing NQA-1 requirements for R&D work.

The work described in this report was assigned the technology level "Applied Research" and was planned, performed, documented, and reported in accordance with Procedure QA-NSLW-1102, *Scientific Investigation for Applied Research*. All staff members contributing to the work received proper technical and quality assurance training prior to performing quality-affecting work.

2.0 Background and Methods

2.1 ILAW Glass Lysimeter Experiments

The ILAW glass lysimeter field studies experiments were conducted in existing lysimeters at the Field Lysimeter Test Facility (FLTF) at Hanford. The FLTF consists of 14 non-weighing lysimeters and four weighing lysimeters installed within a subsurface concrete vault. The size of the lysimeters was 2-m diameter by 3-m deep. Power and water are available at the site. Use of the existing FLTF infrastructure reduced the overall cost of the ILAW glass corrosion field experiments, while satisfying the scientific requirements of the study. Figure 1 shows the surface of the FLTF along with a schematic of how the glass cylinders were arranged in each lysimeter. Three FLTF lysimeters, designated as D-10, D-11, and D-14, were selected and modified for these experiments.

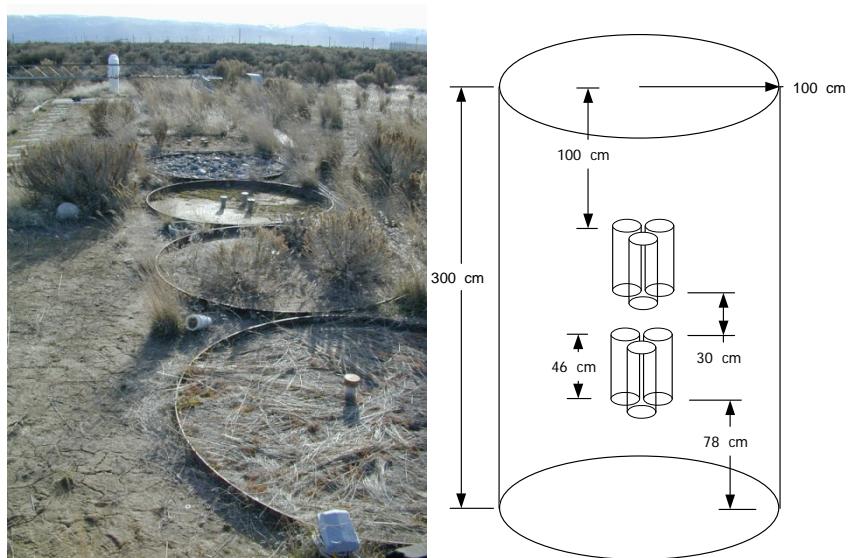

Figure 1. Surface of Field Lysimeter Test Facility (left) Showing Several Lysimeters and a Side View Diagram of ILAW Glass Test Lysimeters Showing that Each Consisted of Two Groups of Three Glass Cylinders at Upper and Lower Levels

The actual glass waste packages to be produced for the IDF will be 213-cm-high cylinders, 122-cm in diameter; however, because of the cost to produce and handle full-size glass cylinders, smaller samples (46 cm high and 20 cm in diameter) were used in the field experiments. These glass samples' dimensions represent a balance between the cost to produce the glass and the desire to represent the key aspects of the flow and transport characteristics of the full-scale facility. Innovatech Services, Inc. prepared twelve HAN28F glass cylinders and six LAWA44 (or equivalent) glass cylinders in 2002 and 2003, respectively (Meyer et al. 2001; McGrail et al. 2003). The glasses were prepared in graphite crucibles, but were transferred to the field in polyvinyl chloride (PVC) containers, which were removed as the glass was buried. The glasses did not include the steel canister of the planned ILAW waste form. A photograph (Figure 2) taken prior to glass burial, illustrates the degree of glass fracturing, which extended throughout the volume of the glass. The fracturing increased the glass surface area and made handling and burial more difficult.

Figure 2. Glass Cylinders Being Buried in a Lysimeter at the Hanford Site

The lysimeter experiments were conducted on the irrigated side of the FLTF; therefore, the experiments received untreated Columbia River water in addition to natural precipitation. The track-mounted overhead irrigation system was set to increase the applied water to three times the average natural precipitation for each month. Irrigation water was typically applied at a rate of 4-mm/hr in increments ranging from 3 to 344-mm per application (Fayer et al. 1999). The lysimeters were watered at 36 cm/year in addition to natural precipitation.

At the time this experiment was set up (FY 2002 and FY 2003), it was expected that the glass waste packages would be placed in the IDF using a hexagonal packing arrangement. The hexagonal packing produces two distinct regions within a layer of the glass cylinders: 1) a central region formed by three adjacent cylinders, and 2) the region along the edge of the layer (or row). Because of the differences in the hydraulic properties of the glass and backfill material, it is anticipated that more water will flow between the glass cylinders than through them. As a consequence, the water content in the region between the cylinders is expected to be higher than the water content outside the row(s) of waste packages. Results from Bacon and McGrail (2001) suggest that the chemistry and transport will also be different in these two regions. To represent both regions in the experimental facility, three glass cylinders were arranged as an equilateral triangle, as shown in Figure 1. The glass cylinders were buried in typical Hanford sandy loam or sandy gravel soils in sets of three per level, two levels in each lysimeter, at depths of 1.0 and 1.76 meters to the tops of the logs. Glass weathering and leachate transport simulation results also suggested that the multiple layers of waste packages will affect the chemistry and transport within the IDF. To investigate these effects in this field experiment, two layers of three glass cylinders are included in the experimental design.

2.2 Lysimeter Sampling and Characterization

After approximately eight years of testing, all three of the lysimeters were excavated and soil and glass cylinders retrieved in FY 2010. The glass samples in one lysimeter (D-14 with LAWA44 glass) were largely intact when dismantled, as compared with the glass samples in lysimeters D-10 and D-11 (HAN28F glass), which were only found in fragments. Portions of the solids from all three lysimeters

were archived for potential future solids and solution characterization. The soil and weathered glass samples were stored in refrigerated storage in the Research Technology Laboratory (RTL) Building at PNNL, and later moved to similar storage in the 331 Building.

During excavation and sampling, large-diameter sediment cores were taken approximately 30 cm from the glass cylinders and small-diameter (19 mm) cores were collected in the volume between the cylinders approximately 1 cm from the glass. These soil samples were collected both for the upper and lower glass cylinder arrays (see Figure 3, Figure 4, Figure 5, and Figure 6). Detailed schematics of the locations, diameters, and lengths of the soil cores obtained from the three lysimeters are found in Figure 7, Figure 8, and Figure 9 for lysimeters D-10 and D-11 with HAN28F glass, and D-14 with LAWA44 glass.

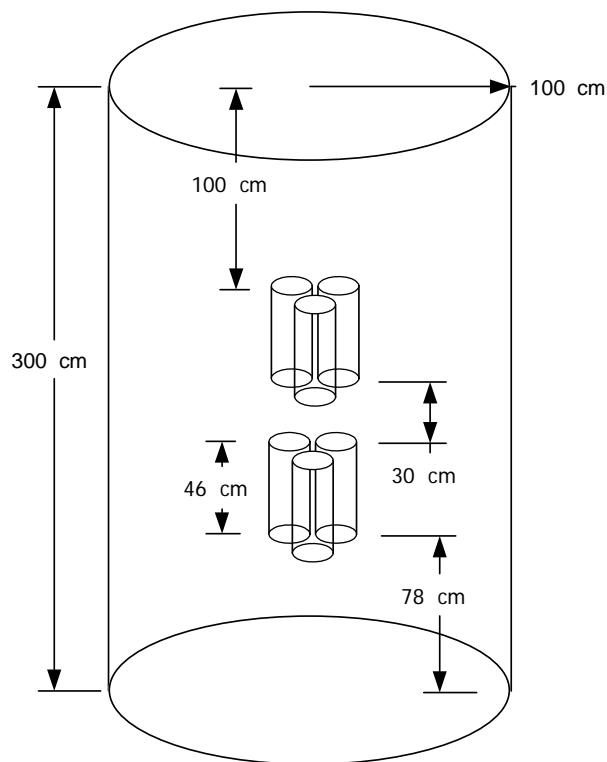

Figure 3. Side View Diagram of ILAW Glass Test Lysimeters Showing that Each Consisted of Two Groups of Three Glass Cylinders at Upper and Lower Levels

For each of the lysimeters, background samples were collected from above the locations of the glass cylinders (indicated as BG in Figure 7, Figure 8, and Figure 9). After the soil cores were brought to the laboratory, 1:1 deionized water extractions were performed. The resulting extracts were analyzed for major and minor cations, anions, pH, and alkalinity. Details of the sample preparation and analysis are available in Pierce et al. (2013). The analytical results of the 1:1 water extracts are also compiled in Pierce et al. (2013).

Selected pieces of glass with sediment attached were subsampled for solid-phase characterization by SEM and XRD. The SEM samples were prepared by first impregnating the sample with epoxy, followed

by cutting with a diamond saw, polishing, and mounting. Samples for XRD analysis were prepared by scraping off sediment attached to the weathered glass samples; the sediment was then powdered and mounted on glass plates.

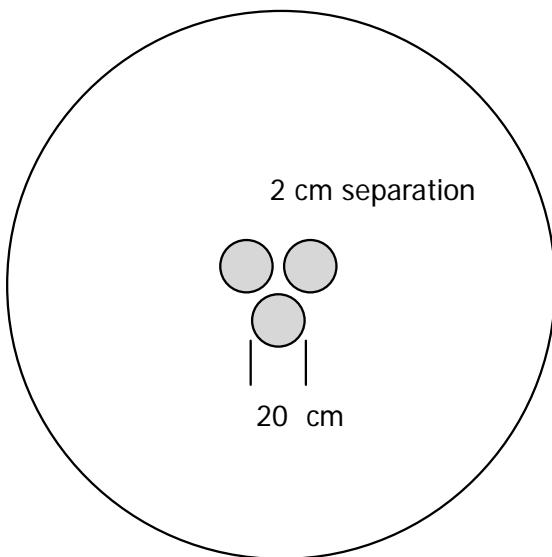

Figure 4. Plan View of Glass Cylinder Arrays in Lysimeters. Sediment samples were collected in two types: large-diameter cores ca. 20–30 cm away from outside of the cylinder array and small-diameter cores between cylinders.

2.3 Geochemical Modeling

Results of the 1:1 water extracts compositions, along with methods used to conduct the extractions, are reported in Piece et al. (2013). Thermodynamic equilibrium modeling was used to calculate mineral saturation indices and to identify solid phases potentially in equilibrium with the 1:1 water extract compositions. For modeling purposes, the redox status of the water extracts was assumed to be approximately in equilibrium with air (an O₂ concentration of 8 mg/L was used in the input). The saturation index is defined as $SI = \log(Q/K_{sp})$, where Q is the activity product and K_{sp} is the mineral solubility product at equilibrium at the temperature of interest. Minerals with SI values near zero (within $\pm \sim 0.5$) are generally considered to be at or near equilibrium, more positive values are considered oversaturated, and more negative values are considered undersaturated with respect to the solution composition. Geochemist's Workbench® version 8.09 (Bethke and Yeakel 2010) was used to calculate the mineral SIs for the leachates. The thermodynamic database “thermo.com.V8.R6+.dat” was used for the modeling calculations. Some of the data in the thermodynamic database were modified to better represent the solubility of expected secondary phases (Pierce et al. 2004). Table 1 shows the thermodynamic solubility constants used to model secondary phase formation in the reaction network developed for LAWA44 glass (Pierce et al. 2004). This set of secondary phases was confirmed to be

largely representative of the secondary phases that form during product consistency tests (PCTs) performed with a large number of glass compositions (Pierce et al. 2013).

Table 1. Thermodynamic Solubility Constants for the Secondary Phase Reaction Network Developed for LAWA44 Glass and Used to Calculate Saturation Indices of Lysimeter Extracts (Pierce et al. 2004)

| Phase | Reaction | Log K (20 °C) |
|--|--|------------------|
| Analcime ($\text{Na}_{0.96}\text{Al}_{0.96}\text{Si}_{2.04}\text{O}_6 \cdot \text{H}_2\text{O}$) | $\text{analcime} + 3.84\text{H}^+ \leftrightarrow 0.96\text{Al}^{3+} + 0.96\text{Na}^+ + 2.04\text{SiO}_2(\text{aq}) + 2.92\text{H}_2\text{O}$ | 9.34 |
| TiO ₂ (am) | $\text{TiO}_2 + 2\text{H}_2\text{O} \leftrightarrow \text{Ti(OH)}_4(\text{aq})$ | -6.56 |
| ZrO ₂ (am) | $\text{ZrO}_2 + 2\text{H}^+ \leftrightarrow \text{Zr(OH)}_2^{2+}$ | -5.47 |
| Calcite (CaCO_3) | $\text{CaCO}_3 + \text{H}^+ \leftrightarrow \text{Ca}^{2+} + \text{HCO}_3^-$ | 1.92 |
| Chalcedony (SiO_2) | $\text{SiO}_2 \leftrightarrow \text{SiO}_2(\text{aq})$ | -3.55 |
| Fe(OH) ₃ (s) | $\text{Fe(OH)}_3(\text{am}) + 3\text{H}^+ \leftrightarrow \text{Fe}^{3+} + 3\text{H}_2\text{O}$ | 9.42 |
| Gibbsite [Al(OH)_3] | $\text{Al(OH)}_3 + 3\text{H}^+ \leftrightarrow \text{Al}^{3+} + 3\text{H}_2\text{O}$ | 8.08 |
| Sepiolite [$\text{Mg}_4\text{Si}_6\text{O}_{15}(\text{OH})_2 \cdot 6\text{H}_2\text{O}$] | $\text{sepiolite} + 8\text{H}^+ \leftrightarrow 4\text{Mg}^{2+} + 6\text{SiO}_2(\text{aq}) + 11\text{H}_2\text{O}$ | 45.83 |
| Zn(OH) ₂ - γ | $\text{Zn(OH)}_2\text{-}\gamma + 2\text{H}^+ \leftrightarrow \text{Zn}^{2+} + 2\text{H}_2\text{O}$ | 11.88 |

3.0 Modeling Results and Discussion

Saturation indices were calculated for 43 1:1 water extract samples. The discussion in this section is focused primarily on phases that are part of the secondary phase reaction network established for LAWA44 glass (Pierce et al. 2004). This secondary phase reaction network is based on modeling of LAWA44 PCT results and was later found to be largely consistent with modeling of PCT results conducted on a large number of other ILAW glass samples (Pierce et al. 2013). Other plausible secondary phases that warrant consideration for possible inclusion in or replacement of other phases within the secondary phase reaction network are also included in the discussion. Phases with saturation indices that are near equilibrium but are likely to be present naturally in the background sediments (e.g., dolomite and coesite) are not discussed.

3.1 Saturation Indices of 1:1 Water Extracts

Saturation indices calculated for the most relevant phases in 1:1 water extracts of selected samples are shown in Table 2, Table 3, and Table 4. Saturation index results for $\text{TiO}_2(\text{am})$, $\text{ZrO}_2(\text{am})$ [(am) indicates an amorphous phase], and sepiolite (Table 1) were not included in the tables because Ti and Zr were not detected above the estimated quantification limit (EQL) in any of the samples and sepiolite was always highly undersaturated. Also included in the tables are the measured pH values of the water extracts. Elevated pH relative to background is a good indicator of an influence from glass dissolution on the sediments. Results for background samples and outer top samples from lysimeter D-14 are shown in Table 2. The outer top samples from lysimeter D-14 are included in Table 2 because these samples do not appear to have been significantly impacted by the glass corrosion and are therefore considered to be representative of background samples. Results for the center samples from lysimeters D-10 and D-11 (HAN28F glass) are shown in Table 3 and center samples from lysimeter D-14 (LAWA44 glass) are shown in Table 4. Besides the background samples, the discussion is focused on the center samples because these samples were located in closest proximity to the glass samples and have the highest potential for impacts from glass dissolution.

Review of the data in Table 2 indicates that for all the background samples, calcite (CaCO_3) and chalcedony (SiO_2) are near-equilibrium in all samples. With the exception of sample D10BG, the aluminum concentrations in all samples were below the EQL. For D10BG, gibbsite was highly oversaturated, but dawsonite appears to be essentially at equilibrium. Iron was below the EQL in all the background samples, so SI values could not be calculated for $\text{Fe(OH)}_3(\text{am})$ [Table 2]. In the absence of sepiolite, several alternative phases were considered for controlling magnesium concentrations. These are magnesite (MgCO_3), chlinochlore-7A [$\text{Mg}_5\text{Al}_2\text{Si}_3\text{O}_{10}(\text{OH})_8$], and saponite-Mg [$\text{Mg}_{3.165}\text{Al}_{0.33}\text{Si}_{3.67}\text{O}_{10}(\text{OH})_2$]. Magnesite was consistently well below equilibrium in all the background samples. SI values for chlinochlore-7A and saponite-Mg could be calculated only for sample D10BG because aluminum was below the EQL for all other samples. For sample D10BG, chlinochlore-7A was highly undersaturated and saponite-Mg was oversaturated. The three zinc-containing phases [$\text{Zn(OH)}_2-\gamma$, zincite (ZnO), and smithsonite (ZnCO_3)] were all unsaturated in the background samples. The pH of the background sample extracts ranged from 7.88 to 8.11, with an average of 8.04.

Table 2. Saturation Indices Calculated for Noteworthy Phases in 1:1 Water Extracts of Background Samples and Outer Top Samples from Lysimeter D-14; Also Included are pH Values of the Water Extracts (blank cells indicate that a phase component was below the EQL, precluding calculation of SI values)

| Phase | Sample ID | | | | | | |
|--------------------------------|-----------|-------|-------|----------|----------|----------|----------|
| | D10BG | D11BG | D14BG | D14SWTOP | D14NWTOP | D14NETOP | D14SETOP |
| Analcime | -1.74 | - | - | - | - | - | - |
| Calcite | -0.55 | -0.37 | -0.36 | -0.25 | -0.33 | -0.32 | -0.30 |
| Chalcedony | 0.18 | 0.20 | 0.27 | 0.35 | 0.33 | 0.32 | 0.32 |
| Fe(OH) ₃ (am) | - | - | - | - | - | - | - |
| Gibbsite | 2.40 | - | - | - | - | - | - |
| Dawsonite | -0.27 | - | - | - | - | - | - |
| Magnesite | -1.62 | -1.37 | -1.26 | -1.26 | -1.27 | -1.26 | -1.19 |
| Clinochlore-7A | -3.86 | - | - | - | - | - | - |
| Saponite-Mg | 0.85 | - | - | - | - | - | - |
| Zn(OH) ₂ - γ | -1.70 | -1.45 | - | -1.37 | - | - | -1.34 |
| Zincite | -1.30 | -1.04 | - | -0.96 | - | - | -0.93 |
| Smithsonite | -1.12 | -1.02 | - | -0.92 | - | - | -0.93 |
| pH | 7.88 | 8.04 | 8.02 | 8.09 | 8.08 | 8.07 | 8.11 |

The center samples collected from the D-10 and D-11 lysimeters are expected to have the highest influence from the glass samples. This is because they are located within the center of the three glass samples (Figure 7 and Figure 8) and these two lysimeters contained HAN28F glass. This glass corrodes relatively quickly (Meyer et al. 2001) and will likely impact adjacent sediments to a greater extent than the LAWA44 glass in the D-14 lysimeter. This is apparent from the pH measurements (Table 3), which range from 8.18 to 9.97 with an average of 9.02. These values clearly indicate that corrosion of the HAN28F glass has measurably impacted the sediments located near the center.

The SI values shown in Table 3 indicate that analcime is essentially at equilibrium in the majority of the samples (5 out of 7). With the exception of sample D1019MMB_ts, gibbsite is significantly oversaturated in all samples. Dawsonite is essentially at saturation for four of the seven samples (D1019MMTOP, D1019MMB_ts, D1019MMB_bs, and D1119MMT_bs) and somewhat oversaturated in three of the samples (D1119MMT_ts, D1119MMB_ts, and D1119MMB_bs). These results indicate that dawsonite may be a more appropriate phase in the secondary phase reaction network than gibbsite under field conditions. This could be due to the presence of a significant pool of calcite in the sediments that provides a continuous source of carbonate, and is in contrast to the PCT tests where carbonate concentrations are limited. At this time the presence of dawsonite at the surface of corroding glass has not been confirmed.

Table 3. Saturation Indices Calculated for Noteworthy Phases in 1:1 Water Extracts of Center Samples from Lysimeters D-10 and D-11 (HAN28F glass); Also Included are pH Values of the Extracts (blank cells indicate that a phase component was below the EQL, precluding calculation of SI values)

| pH | 8.18 | 9.84 | 9.97 | 9.01 | 9.38 | 8.33 | 8.42 |

Chalcedony is virtually at equilibrium for all samples in Table 3. In contrast, calcite is near equilibrium for only three (D1019MMTOP, D1119MMB_ts, and D1119MMB_bs) of the seven samples. Four of the samples (D1019MMB_ts, D1019MMB_bs, D1119MMT_ts, and D1119MMT_bs) are significantly oversaturated with respect to calcite. This oversaturation with respect to calcite is correlated with pH; all of the extracts with oversaturated SI values have pH values of 9 or above. As ILAW glasses corrode, NaOH is released to solution, increasing the pH and sodium concentration. As the sodium concentration increases, it can exchange for calcium on ion-exchange sites of clay minerals, increasing the calcium concentration in solution. As the pH in solution increases, bicarbonate is increasingly deprotonated to carbonate. Both of these processes result in an increase in the SI for calcite. The water extractions were shaken for only one hour. Apparently this was insufficient time for calcite to precipitate and reestablish equilibrium. It is possible that under field conditions, equilibrium would occur because contact times are much greater than that of the extraction tests.

For samples that had quantifiable concentrations of iron, the SI values for Fe(OH)₃(am) all fell within a relatively narrow range (-2.13 ± 0.20). This suggests that these samples are at equilibrium with an Fe(OH)₃(s) phase that has a lower solubility than that assumed for the secondary phase reaction network. This would be consistent with an Fe(OH)₃(s) phase that is more crystalline than the Fe(OH)₃(am) phase assumed for the secondary phase reaction network, and could have been promoted by repeated wet-dry cycles that would have occurred in the lysimeter tests. This would not occur in the PCT experiments because the glass samples are maintained continuously in water.

In four of the seven samples (D1019MMB_ts, D1019MMB_bs, D1119MMT_ts, and D1119MMT_bs) magnesite is essentially at equilibrium. These samples are the samples that have pH values of 9 or above. In the other three samples (with pH values of 8.42 or less) magnesite is significantly undersaturated. In the case of sample D1019MMTOP, saponite-Mg is near saturation and

chlinochlore-7A is highly undersaturated. For samples D1119MMB_ts and D1119MMB_bs, chlinochlore-7A appears to be near saturation and saponite-Mg is highly oversaturated. It is expected that precipitation of secondary phases will be greatest at the glass-water interface, where pH and concentrations of soluble constituents from the glass will be highest. Because of this, it is hypothesized that magnesite is the most probable secondary phase for controlling the concentrations of Mg that leach from glass. At this time the presence of magnesite at the surface of corroding glass has not been confirmed.

Saturation index values calculated for the zinc minerals shown in Table 3 suggest that when there are measurable values of zinc; zincite (ZnO) is closer to being in equilibrium than $Zn(OH)_2\gamma$ for samples D1010MMTOP, D1119MMB_ts, and D1119MMB_bs. For samples D1019MMB_ts and D1019MMB_bs, all the zinc phases are highly oversaturated, with smithsonite ($ZnCO_3$) being the least oversaturated.

Saturation indices calculated for phases of interest in the 1:1 water extracts of center samples from lysimeter D-14 (LAWA44 glass) and pH values of the extracts are shown in Table 4. Based on the pH values measured for these samples, it is apparent that corrosion of the LAWA44 had a minimal effect on the sediments from the D-14 lysimeter. Both calcite and chalcedony are effectively at equilibrium for all four samples, similar to the background samples. Many of the samples had components that were below their EQLs, precluding the calculation of SI values for a number of phases. With the exception of gibbsite, dawsonite and saponite-Mg for sample D1419MMT_bs, nearly all the SI values that were calculated indicated that the remaining phases were undersaturated. The most significant impacts due to glass corrosion were observed in sample D1419MMT_bs, which had an extract pH of 8.33. In this sample both gibbsite and saponite-Mg were significantly oversaturated. Analcime was undersaturated, but not to a great extent, and dawsonite appeared to be essentially at saturation. All these results are consistent with the observation that the impact on lysimeter D-14 sediments due to corrosion of LAWA44 glass was minimal.

Table 4. Saturation Indices Calculated for Noteworthy Phases in 1:1 Water Extracts of Center Samples from Lysimeter D-14 (LAWA44 glass); Also Included are pH Values of the Extracts (blank cells indicate that a phase component was below the EQL, precluding calculation of SI values)

4.0 Conclusions

The results of the geochemical modeling of the 1:1 water extracts suggest that the secondary phase reaction network determined for ILAW glass that were derived from PCT results may be different when glass is buried in Hanford sediment. Several factors may be responsible for this effect. The most important geochemical factor is the availability of carbonate minerals (e.g., calcite) that typically occurs in Hanford sediment. The presence of carbonate-containing minerals in the sediments results in pore waters that are typically in equilibrium with calcite. It is believed that this results in dawsonite [$\text{NaAl CO}_3(\text{OH})_2$] replacing gibbsite within the secondary phase reaction network when glass is corroded in Hanford sediment. It was also found that sepiolite was not likely to form as a secondary phase when glass corrodes in Hanford sediment. Potential alternative phases include magnesite (MgCO_3) and clinochlore [$\text{Mg}_5\text{Al}_2\text{Si}_3\text{O}_{10}(\text{OH})_8$]. The repeated wetting and drying cycles that occurred in the lysimeter experiments may have also had an impact on the nature of the secondary phase reaction network. For example, the solubility of several sparingly soluble metal oxides [e.g., Fe(OH)_3 , $\text{TiO}_2(\text{am})$, and $\text{ZrO}_2(\text{am})$] was much lower in the 1:1 extracts of the lysimeter samples than was found for the PCT experiments.

In order to validate that the alternative secondary phases predicted by the geochemical modeling, it is important to conduct solid-phase characterization to demonstrate their occurrence at or near the surface of the glass. Solid-phase characterization work was done as part of the lysimeter sample characterization completed in FY 2013 (Pierce et al. 2013); however, the results were inconclusive with regards to validating the alternative secondary phases identified by the geochemical modeling of the 1:1 water extracts of the lysimeter samples. To overcome this impediment, a complimentary approach is recommended to optimize our ability to identify the secondary phases that form during glass corrosion in contact with Hanford sediments. This will involve a flow-through column experiment designed to optimize secondary phase formation on glass samples that have been fabricated specifically to optimize sample preparation and characterization methods. Advanced microscopy techniques including SEM-EDS (scanning electron microscopy-energy dispersive spectroscopy), FIB (focused ion beam), and TEM-SAED (transmission electron microscopy-selected area electron diffraction) will be used to characterize the secondary solid phases that form. SEM-EDS can be used to identify likely secondary phases based upon morphology and elemental composition. Once likely secondary phases have been identified by SEM-EDS, phase confirmation can be made using TEM-SAED. The FIB can be used to isolate submicron-size subsamples found using SEM-EDS for TEM analysis (TEM requires very thin samples, typically ~100 nanometers). Once the sample prepared with the FIB has been transferred to the TEM, SAED analysis can be used to identify the specific phase under interrogation.
